An Example of Bernoulli Data

Data (Subsample)

• Patients diagnosed with AIDS in Australia before 1 July 1991

state	sex	diag	death	status	T.categ	age

Let's go through the Bayesian crank

Choose a Model: Bernoulli

Data: *y* = survival status (0 = "A", 1 = "D")

Parameter: θ = probability of "D"

Model equation: $y_i \sim \operatorname{Bern}(heta)$ for $i=1,2,\ldots,N$

• The model states:

the sample data y follows a Bernoulli distribution with the common parameter heta

Bernoulli Likelihood

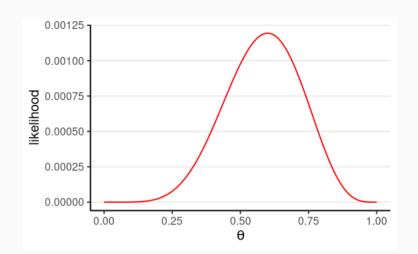

Notice that there is no subscript for θ :

- The model assumes each observation has the same heta
- I.e., the observations are exchangeable

$$P(y_1,y_2,\ldots,y_N)= heta^z(1- heta)^{N-z}$$

- *z* = number of "successes" ("D")
 - *z* = 6 in this illustrative sample

theta	likelihood
0.0	0.00000
0.1	0.00000
0.2	0.00003
0.3	0.00018
0.4	0.00053
0.5	0.00098
0.6	0.00119
0.7	0.00095
0.8	0.00042
0.9	0.00005
1.0	0.00000

Choosing Priors

Specify a Prior

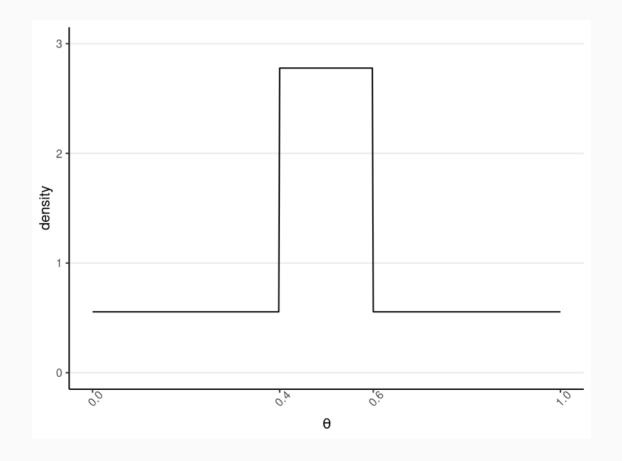

When choosing priors, start with the **support** of the parameter(s)

• Values that are possible

Support for θ : [0, 1]

One Possible Option

Prior belief: θ is most likely to be in the range [.40, .60), and is 5 times more likely than any values outside of that range"

Conjugate Prior: Beta Distribution

Math R Code

$$P(heta \mid a,b) \propto heta^{a-1} (1- heta)^{b-1} I_{[0,1]}$$

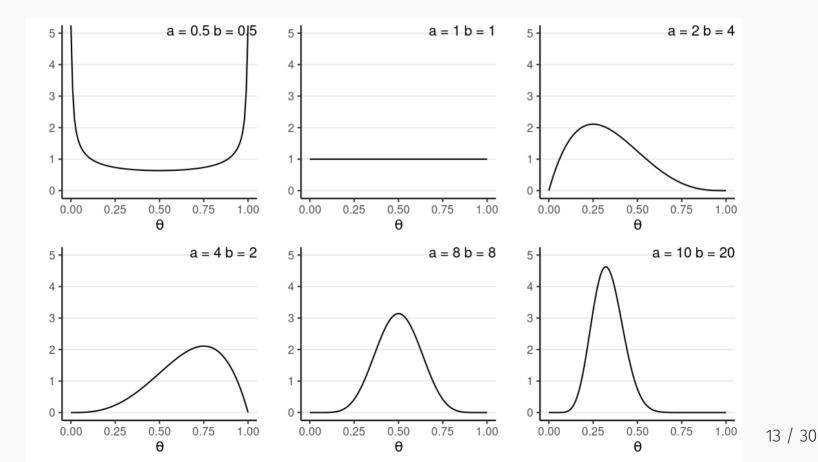

Conjugate Prior: yield posterior in the same distribution family as the prior

Some other conjugate distributions:

https://en.wikipedia.org/wiki/Conjugate_prior#Table_of_conjugate_distributions

Two **hyperparameters**, *a* and *b*:

- a-1 = number of prior 'successes' (e.g., "D")
- b-1 = number of prior 'failures'

When a>b, more density to the right (i.e., larger heta), and vice versa

Mean = a/(a+b)

Concentration = $\kappa = a + b$; $\uparrow \kappa$, \downarrow variance, \uparrow strength of prior

E.g., A Beta(1, 1) prior means 0 prior success and 0 failure

• i.e., no prior information (i.e., *noninformative*)

Notes on Choosing Priors

- Give > 0 probability/density for all possible values of a parameter
- When the prior contains relatively little information

• different choices usually make little difference

- Do a prior predictive check
- Sensitivity analyses to see how sensitive results are to different reasonable prior choices.

Getting the Posterior

Obtaining the Posterior Analytically

$$P(heta \mid y) = rac{P(y \mid heta) P(heta)}{\int_0^1 P(y \mid heta^*) P(heta^*) d heta^*}$$

The denominator is usually intractable

Conjugate prior: Posterior is from a known distribution family

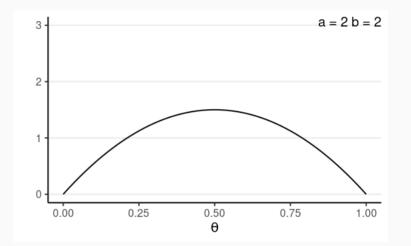

- N trials and z successes
- $\operatorname{Beta}(a,b)$ prior
- $ullet \Rightarrow \operatorname{Beta}(a+z,b+N-z)$ posterior
 - $\circ a + z 1$ successes
 - $\circ b + N z 1$ failures

Back to the Example

N = 10, *z* = 6

Prior: Do you believe that the fatality rate of AIDS is 100%? or 0%?

 Let's use κ = 4, prior mean = 0.5, so a = 2 and b
 = 2

Posterior Beta

 $heta \mid y \sim ext{Beta}(2+6,2+4)$

R Code Density

Summarizing the Posterior

If the posterior is from a known family, one can evalue summary statistics analytically

• E.g.,
$$E(heta \mid y) = \int_0^1 heta P(heta \mid y) d heta$$

However, more often, a simulation-based approach is used to draw samples from the posterior

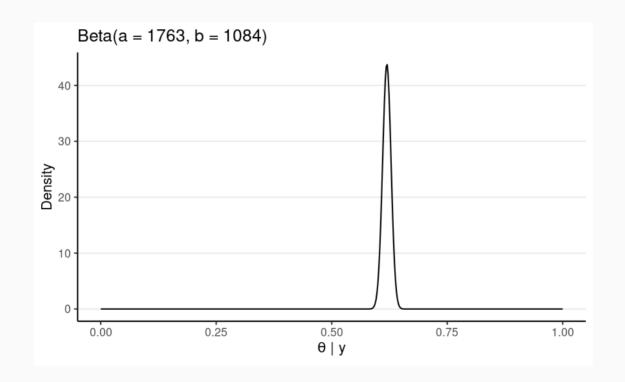

```
num_draws \leftarrow 1000
sim_theta \leftarrow rbeta(1000, shape1 = 8, shape2 = 6)
```

Statistic	Common name	Value
mean	Bayes estimate/Expected a posteriori (EAP)	0.563
median	Posterior median	0.567
mode	Maximum a posteriori (MAP)	0.577
SD	Posterior SD	0.126
MAD	MAD	0.13
80% CI	(Equal-tailed) Credible interval	[0.398, 0.727]
80% HDI	HDI/Highest Posterior Density Interval (HPDI)	[0.404, 0.733]

Use the Full Data

1082 A, 1761 D ightarrow = 2843, z = 1761

Posterior: Beta(1763, 1084)

Posterior Predictive Check

Posterior Predictive Check

 $ilde{y}$ = new/future data

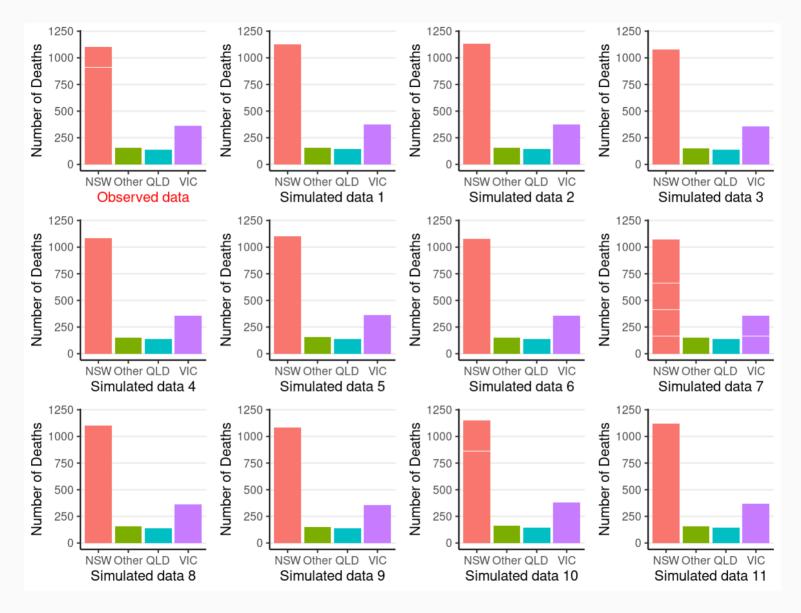

Posterior predictive: $P(ilde{y} \mid y) = \int P(ilde{y} \mid heta, y) P(heta \mid y) d heta$

Simulate θ^* from posterior --> for each θ^* , simulate a new data set

If the model does not fit the data, any results are basically meaningless at best, and can be very misleading

Requires substantive knowledge and some creativity

• E.g., are the case fatality rates equal across the 4 state categories?

Posterior Predictive Check

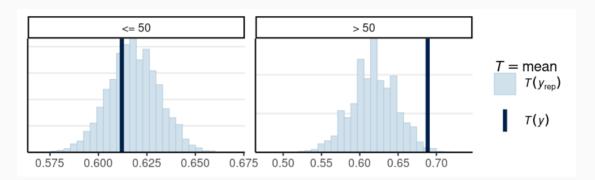

Some common checks:

- Does the model simulate data with similar distributions as the observed data?
 - e.g., skewness, range
- Subsets of observed data that are of more interest?
 e.g., old age group
 - If not fit, age should be incorporated in the model

See an example in Gabry et al. (2019)

Using bayesplot

Plot R code

Darker line = observed proportion of "D"; histogram = simulated plausible statistics based on the model and the posterior

The model with one-parameter, which assumes exchangeability, does not fit those age 50+

- May need more than one heta

Other One-Parameter Models

Binomial Model

- For count outcome: $y_i \sim \operatorname{Bin}(N_i, \theta)$ $\circ \theta$: rate of occurrence (per trial)
- Conjugate prior: Beta
- E.g.,
 - $\circ \; y$ minority candidates in N new hires
 - $\circ \; y$ out of N symptoms checked
 - \circ A word appears y times in a tweet of N number of words

Poisson Model

- For count outcome: $y_i \sim \operatorname{Pois}(heta)$ \circ heta: rate of occurrence
- Conjugate prior: Gamma
- E.g.,
 - \circ Drinking y times in a week
 - $\circ \; y$ hate crimes in a year for a county
 - $\circ \ y$ people visiting a store in an hour
